Valuable Words: The Price Dynamics of InternetDomainNames

Thies Lindenthal

Massachusetts Institute of Technology, Center for Real Estate, 120
Massachusetts Ave, Cambridge, MA 02139. E-Mail: *thilin@mit.edu*.

Abstract

This paper estimates the first constant quality price index for Internet domain names. The suggested index provides a benchmark for domain name traders and investors looking for information on price trends, historical returns and the fundamental risk of Internet domain names. The index increases transparency in the market for this newly emerged asset class. A cointegration analysis shows that domain registrations and resale prices form a long-run equilibrium and indicates supply constraints in domain space.

The study explores a large dataset of domain sales spanning the years 2006-2013. Differences in the quality of individual domain names are controlled for in a hedonic repeat sales regressions.

Acknowledgements

I would like to thank Prof. David Geltner (MIT) for generously sharing his advice and feedback. Tim Schumacher and Ulrich Essmann are thanked for granting research access to the unique database of domain transactions facilitated by Sedo.com.

Internet domain names bring the location back to the otherwise location-less Internet economy. A domain name provides a virtual street address for any website or service on the Internet. It is

comparable to a tract of land on which a business or just a private homepage can be built on. This space-network analogy is as old as the World Wide Web and numerous terms related to the Internet exhibit a spatial connotation: Labels for technical network addresses, for instance, are called *domains*, users are *visitors*, Internet browsers have been baptized *Navigator* or *Explorer*, *websites* are *home* pages, users communicate in chat *rooms* the list can be easily extended.

Understanding domains as a novel form of land offers the opportunity to transfer established theoretical and empirical frameworks for the pricing of land into virtual space. Theoretically, Alonso-Muth-Mills models of urban layouts (Alonso,1964;Mills,1972;Muth,1969) explain differences in land rents by differences in the distance to jobs or amenities. Applying this reasoning to domains, the price of a domain is hypothesized to depend on its proximity to potential users. Since a voyage on the world wide web usually begins with the user entering the domain name of the desired website into her web browser, distance to the user can be seen as the effort a user is required to make to correctly remember and type a domain name. An appealing domain name like *Apple.com* is easy to recall and quickly entered. In this sense, an intuitive domain name is like a convenient down-town address linked to excellent transportation systems. Long or cryptic domain names are more burdensome, which is comparable to a longer commute to a location somewhere in the outskirts.

Ieong et al.(2012) provide a similar, albeit non-spatial explanation for the value of domains. They show that domains help users to evaluate the reliability of search results from online search engines. Domains serve as *brands* for the displayed information. Based on this line of thought, differences in domain prices could also stem from the brand-potential inherent in the domain name. Again, the catchy and easy to remember names will sell at a premium above registration costs.¹

Differences in location and brandability fuel a heated race for the shortest and most memorable domain names that sprung up since the very first domain was created in March 1985. By now, more than 240 million unique domain names are registered ([Verisign, 2012](#)) with no end of growth in total numbers in sight. An active secondary market facilitates investments in domains. Exclusive domains oftentimes trade for 5 or 6 figure dollar amounts, and some for even more. The current record in reported sales prices is the widely covered 13 million US dollar transaction of *sex.com* in 2010². Trading of and investing into domains has quickly evolved from a geeky pastime of a few to the serious bread and butter industry feeding hundreds of professionals today.

The focus of this paper is to estimate the first constant quality price index for Internet domain names. It adapts an empirical framework borrowed from real estate research which is suitable for valuing infrequently traded and non-standardized assets like houses, antiques, pieces of art or, by analogy, virtual locations. The linguistic nature of Domains causes substantial heterogeneity in their quality, which makes domain names very comparable to traditional asset classes where the intrinsic value of an asset is not directly observable as well.³ The index spans 7 years and is updated on a monthly basis.

Despite all rapid growth in the last decade, domain names are still a relatively small investment class that lacks any information on its inherent risk and return profile.⁴ Market participants and investors simply do not know whether domain names are a good investment. Did domain holdings deliver positive returns in the last years at all? How big were any returns?

Rational investors evaluate return and risk of their holdings simultaneously. The market index is the best proxy fundamental risk of domain names. The price volatility of a market portfolio hypothetically containing all domain names cancels out any domain-

specific volatility. The fundamental or market risk of domains can be compared to the risk of an investors portfolio, which puts any return on this portfolio into a risk-adjusted perspective. Furthermore, the fundamental risk of domains can be compared to the risk of other investment classes like stocks, bonds or real estate.

The massive increase in virtual space and new extensions (ICANN Internet Corporation For Assigned Names and Numbers, 2012a) scheduled for 2013 and 2014 by the Internet Corporation for Assigned Names and Numbers (ICANN), is, among other reasons, motivated by a perceived scarcity of domains. This paper provides first evidence that supply of domain space is currently constrained indeed.

Finally, any cautious economist will surely ask: Are domains names for real or just another fad? Or does an economic rationale justify the prices paid? A comparison of domain prices to share price indices for IT companies shows that domains are not a totally detached new economy. The value of locations on the web is closely correlated with e. g. the NASDAQ 100.

The remainder of this paper first presents a primer on Internet domain names, including a brief introduction on the nature of domain markets. Section 3 provides an overview of the data this study analysis relies on. This motivates the choice of an adequate index estimation methodology in the subsequent section. Section 5 discusses the empirical results leading to general conclusions.

I A Primer on Internet Domain Names

Domain names make the Internet navigable for humans. All servers, computers and other devices linked to the Internet use a unique

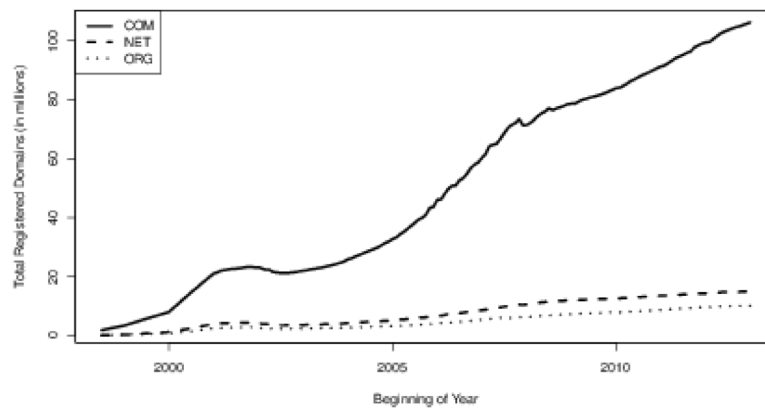

Internet Protocol (IP) number as their address within the network. Typing 74.125.226.201 into the address bar of a web browser will lead to the website of a well known search engine from California. Since IP numbers are hard to remember for Internet users, the Domain Name System (DNS) provides shortcuts, assigning more memorable domain names to the underlying IP numbers.

Each domain name consists out of at least two components: Top Level Domains (TLD) structure the overall name space into a limited number of subsets that either have a global scope (gTLD) like COM, NET, ORG or that are country specific (ccTLD) like DE, FR, NL.⁵ Each TLD is subdivided into Second Level Domains (SLD) that can consist out of letters, numbers and hyphens only. Spaces are not allowed. The combination of a TLD and SLD, separated by a colon, is commonly referred to as an Internet domain name. It cannot exceed 67 characters in total.⁶

From a lawyers perspective, it is not resolved yet whether a domain name is an intangible asset or just a contractual right (Burshtein,2005) in practice, the case is clear: domains are treated and traded like assets.

The primary market for domain names resembles the land rushes in 19th century America (Lindenthal,2011). The general rule is: Whoever files a registration for a domain first receives this domain. No costs but a modest registration fee to the TLD registry are incurred. As a result of this liberal first-come-first-serve approach, the number of domain names grew rapidly in the last decade. Figure1 visualizes the growth in the total number of registered .COM/.NET/.ORG domains since 1998.

Figure1: Number of registered domain names for selected Top Level Domains

Notes: A heated race for the best domain names sprung up since the first domain name in history, symbolics.com, was created in March 1985. By now more than 246 million unique domain names are registered ([Verisign, 2012](http://www.verisign.com)) with no end of growth in total numbers in sight.

Data from Zooknic (<http://www.zooknic.com>) and ICANN (<http://www.icann.org/en/resources/registries/reports>).

A domain must be renewed in periodic intervals, again incurring a fee. As long as the renewal fees are taken care of, the domain owner enjoys full ownership benefits, including the possibility to rent out the domain or to sell it at the secondary market. Domains that do not get renewed become available for registration again. About 27 percent of .COM/.NET domains were not continued in 2011 ([Verisign, 2012](http://www.verisign.com)) but handed in again. Alternatively, owners can sell domains they do not wish to develop themselves in secondary markets.

The majority of re-sales of domains are closed privately or through competing trading platforms that offer marketing and transaction handling services to buyers and sellers. No trading licenses or other formal requirements restrict access to the market.

Estimating the size of secondary markets is difficult as no central registry explicitly keeps track of domain sales. The Internet Corporation For Assigned Names and Numbers (ICANN) reports 8 million transfers of .COM/.NET domains for January 2011, which is the

upper bound of total sales as this number contains many not-for-sale transfers. The number of domain transfers across whole-sale registration companies could serve as a better proxy for domain transactions. In January 2011, 0.65 million .COM or .NET domains were transferred from one registrar to another (ICANN Internet Corporation For Assigned Names and Numbers,2011).

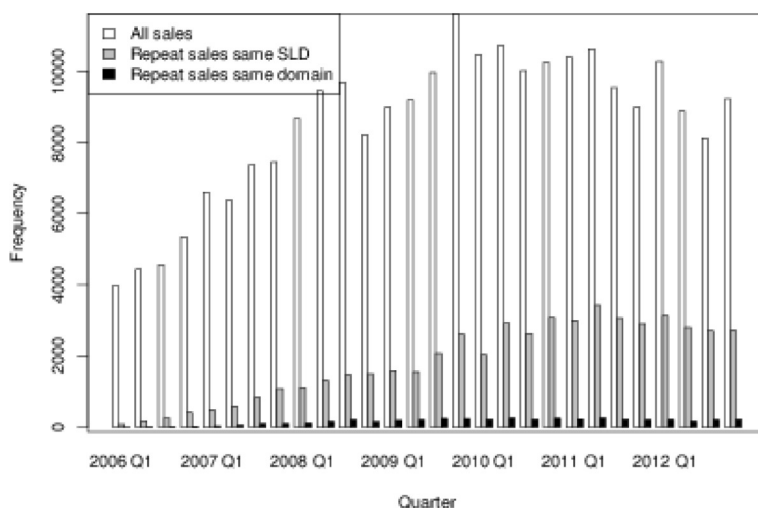

Scenarios under which domains trade are manyfold. Entrepreneurs who registered a domain to host a new website sell the domain when the intended project does not materialize.⁷ Owners of an operating website might move its content to a different location in case they receive a favorable purchase offer from other developers who can utilize the domain name more effectively. Finally, domain investors have registered wide swathes of address space hoping to resell domains at a profit to end users later.

In all these cases, buyers and sellers negotiate freely and it is reasonable to assume that prices are distributed around fair market value. However, domain speculation also has a dark side in which so-called typosquatters register misspellings of popular domains (Edelman and Moore,2010;Banerjee etal.,2011) or trademarks in order to benefit from advertisements placed at these domains. Although legal remedies⁸ exist to protect domain or trademark owners against these registrations in bad faith, oftentimes the safest and easiest solution is simply to purchase the domain from the perpetrator. Such transactions will not represent fair market values. Fortunately, the domain marketplace providing for the data for this paper screens the domains listed for sale and rejects typosquatters. This ensures fair transactions and a clean data set.

II Data

This study relies on a dataset of all domain transactions facilitated by the trading platform Sedo.com, which is one of the largest domain market place in the world based on completed transactions and sales volume. The sample comprises of 243,291 transactions for the period from January 2006 through January 2013. Figure2 presents the number of observations per quarter. The sample is not uniformly distributed in time, with more transactions taking place in later quarters.

Figure2: Distribution of sales per quarter (2006Q1-2012Q4)

Notes: The sample is not uniformly distributed in time, with more transactions taking place in later quarters. The number of pairs of sales sharing the same SLD is about one fifth of the number of sales. For sales pairs of exactly the same domain, the count is only 2 percent of the number of sales.

Completed transactions are a small subset of all domains offered for sale. In 2010, about 14 million domains were listed at Sedo.com in contrast to just 44,000 sales in that year. The low initial registration fee of just a few dollars per domain and the potentially high returns in case of a successful sale warrants a lottery-like market where domains are registered and put up for sale on a large scale. A back-of-an-envelope calculation illustrates that domain trading is profitable at the aggregate level: Multiplying the median transaction price in 2010 (500 USD) by the number of transactions (44,000) gives a total turnover that is several times bigger the sum of all registration and renewal fees (6-10 USD per year and domain). For the data at hand, Sedo.com's fee structure is likely to induce substantial cheating as sellers first use the platform for marketing purposes but close the deal privately in order to avoid the fees due when domains change hands through the platform's official channels causing too low sales figures.

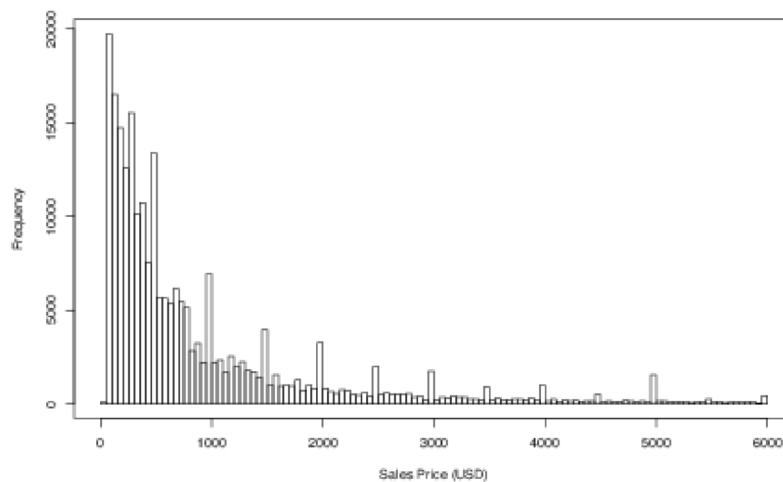

In May 2011, 28 percent of all sales are closed at a fixed price set by the seller in advance while for 42 percent of trades the price is set in bilateral price negotiations, where the buyer has to give a first price quote. 13 percent of transactions are initiated by professional brokers affiliated with Sedo.com. 17 percent of sales were closed in auctions. The selling mechanism is not a true hedonic characteristic since it is not necessarily linked to the quality of the domain name. Still, including this information into a hedonic framework improves the model fit as Bulow and Klemperer(1996) show that auctions lead to higher transaction prices than negotiations with one less bidder.

All transactions that include a website or other content beside the naked domain name are excluded from the sample, since disentangling the value of the domain from other factors like an existing user base, software, or other content is impossible.

The sample does not contain any information on the characteristics of buyers and sellers.

The median transaction price is 500 USD. The sales price distribution has an enormous right tail, with 12 domains exceeding one million USD. The biggest fish in the sample is *sex.com*, which has been sold for 13 million USD in November 2010. The average SLD consists out of 9.87 characters, 1.8 percent of the samples SLDs contain diacritic characters, 5.68 percent consist of at least one digit, while 9 percent are split by dashes.

Figure3: Distribution of transaction prices

Notes: The top 5 percent of transaction prices is not shown. The median sales price is 500 USD while the maximum price in the databases is 13 million USD.

Table1: Summary statistics

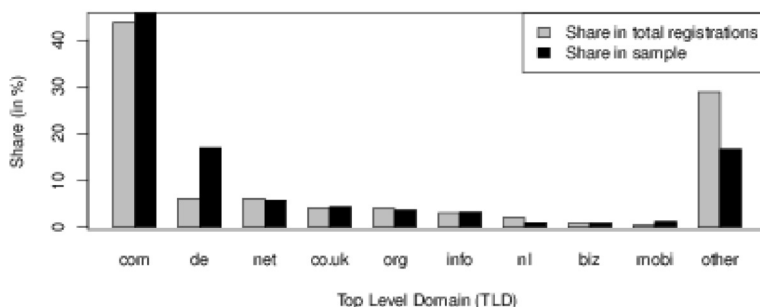

<i>Sample</i>	<i>N</i>	<i>Length</i>	<i>Share of domains containing</i>			
			<i>in chars.</i>	<i>digits</i>	<i>dashes</i>	<i>diacritics</i>
All COM domains	107 M	14.36	7.00 %	11.52 %	0.88 %	
Domains listed for sale	16 M	12.59	5.30 %	11.47 %	1.76 %	
Domains sold (Sedo.com)	243,291	9.87	5.68 %	9.00 %	1.80 %	
Repeat sales same SLD	52,811	7.62	5.44 %	3.81 %	1.56 %	
Repeat sales, same SLD and TLD	4729	7.48	14.65 %	4.67 %	1.18 %	

Notes: Domain listings and sales are taken from Sedo.com (2006-2013) and are therefore a subsample of all sales and listings. Sold domains are on average shorter than both listed domains and domains registered and contain less digits and dashes than registered domains. This suggests a filtering based on domain quality: better domains trade more frequently.

The most senior COM/NET domain in the sample was registered in early 1989. The vintage of the domains slowly deteriorates throughout the years. In 2006, the average year of first registration was 2003 compared to 2005 in 2010.

In total, 156 different TLDs are present in the database. Figure4 compares the share of the 9 most frequent TLDs within the sample with their share in the universe of registered domains. COM accounts for almost half of all domains, followed by DE, NET, ORG, and UK. The weights in the sample do not divert much from the true weights based on total registrations for most TLDs. The country-code top level domain DE is over-represented, probably due to Sedos strong roots in the German market. Less popular domains that are subsumed under the label other are less prominent in the sales sample. The wide distribution across international TLDs is a unique feature of sales data from Sedo.com besides the outstanding size of the sample.

Figure4: Distribution of Top Level Domains (TLD)

Notes: The red bars represent the weight of all domains under a TLD versus the total universe of registered domains. The blue bars show the weight of a TLD in the sample. In total, 156 different TLDs are present in the database (top 9 shown above). The country-code top level domain .DE is over-represented, probably due to SEDOs strong roots in the German market.

Data on total domain counts from [Denic\(2011\)](#).

III Methodology

Domain names are unique: By definition, it is not possible to have the same combination of top level domain (TLD) and second level domain (SLD) twice. When estimating the value of a domain name, one cannot draw a direct comparison to recent transactions of exactly the same (or at least very similar domains), as it is common for pricing standardized goods like stocks or bonds.

Taking the average of transaction prices gives a first indication of price developments in the market for domains but does not control for quality differences in the domains sold. If there is a time period in which many high-quality domains are sold, the average transaction price will increase, regardless of any true trend in prices. Median based indices are less sensitive to extreme values but suffer from the same systematic shortcoming of disregarding the characteristics of the underlying transactions. Putting it differently, one is comparing apples to oranges.

Two general methodologies are commonly used to price non-standardized assets like real estate or art. The first one, the so-called hedonic regression analysis, explains the price of an asset by a set of quality variables that describe the characteristics (hedonics) of that asset. For example, when investigating the sales prices of cars,

hedonic characteristics one might think of are the mileage of the car, the year of production, the manufacturer etc. Differences in quality will be captured in the regression coefficients of the hedonic variables, while a general price trend can be separated from potential changes in the underlying quality of the traded assets. The overall explanatory power of this approach depends on how well the hedonic variables capture the price-relevant characteristics of the asset. For domains, this method is not feasible as only very few dimensions of the quality of domains can be described by quantitative variables.

Alternatively, the repeat sales methodology (Bailey et al., 1963) controls for quality by tracing individual assets in time, comparing each transaction to previous transactions of the very same asset. It assumes that the quality of the asset does not change between the two sales. While this is probably the most direct form of making sure to compare apples to apples, it disregards all information on transactions that are sold only once. Furthermore, repeat sales can cause a sample selection bias, as domains that trade more than once could be systematically different from domains that trade only once.⁹ In practice, this approach is suitable for samples of non-standardized goods that provide sufficient numbers of repeat sales.

This paper follows the Hedonic Repeat Sales (HRS) methodology, first suggested by Shiller (1993). HRS combines the advantages of having individual dummies for each SLD and a hedonic classification of the highly standardized TLD. It utilizes the simplicity of repeat sales estimation while alleviating the problem of sample selectivity. Using repeat sales avoids the problem of identifying explanatory variables on domain quality and circumvents the omitted variables problem which is very pronounced for domains.¹⁰ Including the hedonic characterization for the TLD extends the number of observations entering the regression more than 10 times from 4,729 repeat sales of exactly the same domain to 52,811 pairs with the same SLD. To give an example: A repeat sales regression only considers repeat transactions

of exactly the same domain (like XYZ.COM) while a hedonic repeat sales approach includes single sales that share the SLD but have different TLDs (like XYZ.COM and XYZ.NET).

Conceptually, the sales price P of domain i is split into three components:

$$P_{i,t} = SLD_i + TLD_i + D_t, \quad (1)$$

where SLD and TLD capture the quality of each SLD and TLD. Time dynamics enter the equation through D_t . Differencing transactions that share the same SLD cancels out the SLD component:

$$P_{i,t1} - P_{j,t2} = (SLD_i - SLD_j) + (TLD_i - TLD_j) + (D_{t1} - D_{t2}) = TLDCombi_{i,j} + D_{t1-t2}, \quad (2)$$

which leads to an equation that can be empirically tested in a regression:

$$\ln(P_{i,t2}) - \ln(P_{j,t1}) = \sum_{k=1}^{K} \gamma_k TLDCombi_{k,i,j} + \sum_{t=2}^T \beta_t D_{t,i,j} + \epsilon_{ij}, \quad (3)$$

where the difference in the natural logarithm of prices from transaction i and j is the dependent variable, explained by a set of time dummies D_t and TLD combination dummies. For each pairwise combination k of TLDs in the sample, $TLDCombi_k$ is defined to be one if TLD_i equals the first element and TLD_j equals the second element of k , and zero otherwise. K is the squared number of unique TLDs in the sample. The time dummy D_t is defined in a Bryan and Colwell(1982) way, as described in Geltner(1997). For each time period between t_1 and t_2 , D_t is set to 1. When only parts of a given time period fall between the two sales dates, the value for D_t is scaled down accordingly. If t_1 , for instance, is June 30, 2009, the annual dummy for 2009 will be set to 0.5, for November 31st it will be adjusted to 1/12. The default value is 0. This methodology provides end-of-time-period

return estimates and avoids averaging within each time period (Geltner,1997).

α_k and β_t are regression coefficients. The relative price differences between TLDs are kept constant in time. For each pair of TLDs (a, b) , the coefficients $\alpha_{k=(a,b)}$ are restricted to be $-\alpha_{k=(b,a)}$. The error term $\epsilon_{t,i,j}$ is assumed to be independently and identically distributed.

The goal of this paper is the estimation of an index that can be updated frequently and that still provides reliable index figures not subject to excess volatility. When estimating a high frequency index, the number of observations per time period will be low. This causes the resulting index to be sensitive to noise, resulting in excessively volatile index estimates with low signal/noise ratios. Goetzmann(1993) further shows that repeat sales regressions suffer from spurious negative autocorrelation in the estimated return series and an excess return volatility, especially at the beginning and at the end of the series where the data thin out.

Imposing a time structure on the time coefficients β_t reduces the effect of transaction price noise in thin markets. Goetzmann(1993) therefore suggests a Bayesian shrinkage techniques where the log levels are modelled as a random walk with drift process. Francke(2010) generalizes this approach and extends the random walk with drift model to a structural time series model.

This paper follows a novel frequency conversion approach suggested by Bokhari and Geltner(2010). In a first step, lower frequency indices are estimated staggered in time. For the domain name index, we estimate twelve annual indices based on (3), each starting in a different month.¹¹ Applying a generalized inverse estimator converts these annual indices to a monthly return series.

The Bokhari/Geltner approach relies on sympathetically few assumptions. Any index estimation technique can be used in the first stage. No time structure on the high frequency time coefficients need to be formalized. The resulting higher frequency index has a better signal-to-noise ratio than directly estimated high frequency indices. In addition, no time lag is introduced. Bokhari and Geltner(2010) provide a very detailed step-by-step explanation of the methodology.

IV Results

Table2 presents the coefficients of one of the 12 first stage regressions based on Equation 3. In total, 12 annual indices are estimated based on the seven time dummies (Year 17), each index starting at a different month of the year (the table shows first estimation for index starting in January only). The lower panel contains coefficients for the pairwise TLD comparisons *TLDCombi*. The Adjusted R^2 for the first stage regressions is 0.32.

Notes: The estimation of Eq. (3) contains 7 annual dummy variables. In total, 12 annual indices are estimated, each starting at a different month of the year (table shows first estimation only). A second step converts the staggered annual indices to a index at monthly frequency (Bokhari and Geltner,2010). The lower panel contains coefficients for the pairwise TLD comparisons *TLDCombi*. The Adjusted R^2 is 0.32.

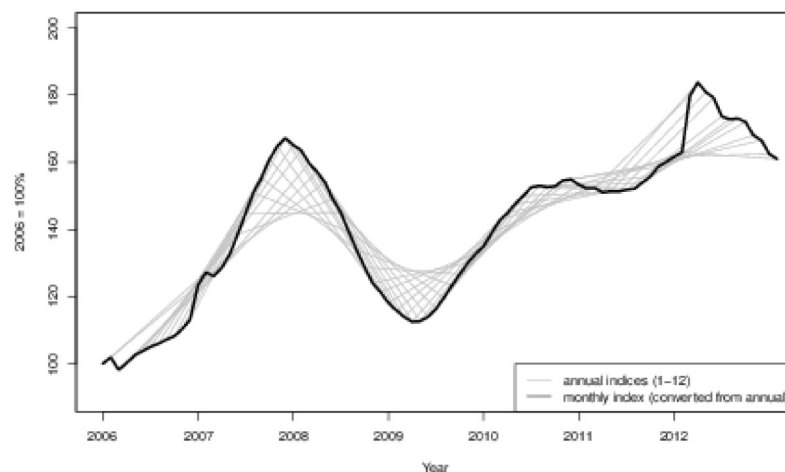

In a second step, the 12 annual indices are converted to one index at monthly update frequency. All 13 indices are displayed in Figure 5. The solid black line represents the resulting aggregate price trend at a monthly frequency while the first stage indices are depicted by thin lines. Overall, the domain price index increased by 63 percent from January 2006 through January 2013. The average historic return is 0.72 percent per month with a standard deviation of 2.6 percent.

Table 3 presents the Internet Domain Name Index (IDNX) estimates on a monthly frequency for the years 2006 through 2013. Internet domain names gain in value in 2006 through 2007, with prices peaking in November 2007 (+67percent) before losing one third of their value in the subsequent 16 months. Since then, domain prices

regained their strength, climbing to an all-time high in March and April 2012 (Figure6), again followed by a sharp drop. The pronounced cycle demonstrates that domain names offer attractive investment opportunities to the skilled (or lucky) investor that can identify boom and bust phases in advance.

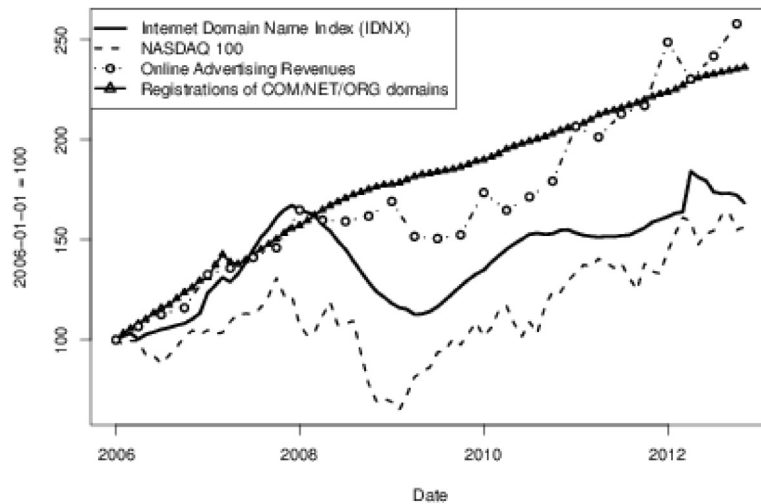

These results also show that domain names are risky investments the observed bust phase in 2008 wiped out a large share of market value before bouncing back. There are simply no risk-free gains to be made, no free lunch waiting to be consumed. In addition, liquidity in the market dries up just when it is needed most. Investors trying to liquidate their domain name holdings in 2008 had to find a buyer in relatively thin markets, indicated by reduced total transaction numbers during the bust period (Figure2).

Figure5: Staggered annual indices for all TLD and resulting monthly index

Notes: Twelve annual indices based on (3) are estimated, each starting in a different month. Applying a generalized inverse estimator converts these annual indices to a monthly return series (black line).

Figure6: Price dynamics of Internet domain names compared to NASDAQ 100

Notes: Domain prices have an economic foundation. This figure suggests that domain prices changes are very similar to changes in the NASDAQ 100 index, which covers the 100 largest technology companies listed on the NASDAQ stock market. When the Internet economy is expanding, domain names as a production factor are in high demand as well.

The most important source of income for the majority of Internet enterprises is revenue from online advertisements (Time series for online advertisement revenues in the United States based on [IAB, 2012](#)). In 2006/2007, both domain prices and ad revenues move at the same speed. After the dip caused by the global financial crisis, the recovery takes place at similar rates again. However, from 2010/2011 onwards, ad revenues outgrow domain prices, which indicates that most domain owners do not benefit from the incoming funds as much as before.

Domain prices have an economic foundation. They are not detached from the economy in general. On the contrary, Figure6 plots the NASDAQ 100 index, which covers the 100 largest technology companies listed on the NASDAQ stock market along IDNX. The close resemblance of both lines indicates that domain price changes are very similar to changes in the IT economy. The estimated correlation on monthly changes in both indices indeed is 0.19. When the Internet

economy is expanding, domain names as one production factor are in high demand as well.

Furthermore, one can observe a close link between prices paid for domain names revenues from online advertisement, which form an important source of income for the majority of Internet enterprises (Evans,2009). This dependency is visible in the close co-movement of advertising revenues tracked by IAB(2012) and domain prices in the boom years before the 2008. Subsequently, the financial crisis paused any growth in advertisement spendings and sent domain prices on a downward trajectory. In the time period from 2009 through 2010, advertising revenues and domain prices jointly recovered: From June 2009 through January 2011, advertisement revenues expanded by 37 percent and domain prices by 32 percent. However, starting in the second half of 2010 domain prices exhibit a lower growth rate and cannot keep pace with rapidly expanding advertising money.

The number of registered domain names and the level of re-sale prices are two different views on the overall demand for domain names the first tracking the primary domain market and the latter the secondary or re-sale market. Eyeballing Figures 6 and 7 suggests a co-movement of changes in prices and domain registrations, indicating an equilibrium between registrations and prices. Whenever prices are high, more domains get created and in times of falling prices the growth of registrations also comes to a halt.

We conduct a co-integration analysis¹² to formally tests for any long-run equilibrium between the primary and secondary market. Following Pfaff(2008) in notation, first a general vector autoregressive (VAR) model is defined as:

$$y_t = A_1 y_{t-1} + \dots + A_p y_{t-p} + B X_t + u_t \quad (4)$$

where y_t is a vector of the quarterly changes in prices in the secondary domain market (estimated by IDNX) and changes in the number of

registrations in the primary domain markets for COM, NET and ORG domains and p the number of lags. The A_i are (2×2) coefficient matrices for $i = 1, \dots, p$ and u_t is a 2-dimensional white noise process. Quarterly changes in revenue from online advertising and seasonal dummies enter the equation as exogenous variables (X_t). Based on this VAR, a transitory Vector Error Correction Model (VECM) can be specified as:

$$\Delta y_t = \alpha\beta' y_{t-1} + \Gamma_1 \Delta y_{t-1} + \dots + \Gamma_{p-1} \Delta y_{t-p+1} + \xi X_t + u_t \quad (5)$$

where

$$\Pi = \alpha\beta' = -(I - A_1 - \dots - A_p) \quad (6)$$

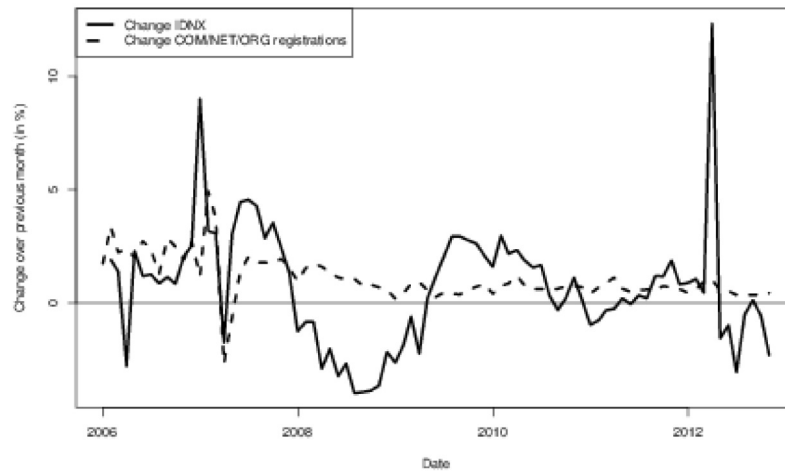

and

$$\Gamma_i = -(A_{i+1} + \dots + A_p) \quad (7)$$

and $i = 1, \dots, p - 1$. In case the series are cointegrated, the matrix will have a reduced rank (Johansen, 1988).

Table 4 features the test statistics and critical values for the Johansen cointegration test.¹³ Based on these values, the hypothesis of having rank 0 can be rejected at all levels of confidence while a rank of 1 cannot be rejected. In other words: Changes in prices and registrations are linked. In addition, the regression coefficients presented in Table 5 indicates that deviations from the long run equilibrium between primary and secondary markets are corrected by adjustment in registrations, not prices, and that the secondary market responds to changes overall demand for domains faster than the primary market.

Figure 7: Cointegration of primary and secondary domain markets

Notes: The figure shows the monthly change for resale prices of domain names as estimated by IDNX (solid line) and the growth in total registrations for COM, NET, and ORG domains (dashed line). Overall, the variance in secondary market price growth is higher than the variance for the primary market of registrations. Furthermore, price swings precede registrations, indicating that secondary markets respond faster to changes in general demand for domains than the primary market.

Table4: Values of test statistic and critical values of Johansen test

Rank Cointegration Vector	Test Statistic	Critical Values		
		10 %	5 %	1 %
$r = 1$	2.43	7.52	9.24	12.97
$r = 0$	24.58	13.75	15.67	20.20

Note: The hypothesis of the cointegration matrix having a rank of 0 can be rejected at all levels of confidence while a rank of 1 cannot be rejected. This indicates that both series are cointegrated.

Table5: Regression coefficients for unrestricted VECM

Variable	$IDNX_t$	$Reg.COMNETORG_t$
Constant	0.007	0.006 *
Ad. Rev.	-0.389	-0.028

$Reg.COMNETORG_{t1}$	0.016	-0.337 ***
<i>Adj. R²</i>	0.12	0.73

Note: The significance levels (P-values) are indicated by *** for 0.01, ** for 0.05, and * for 0.1. None of the coefficients for $IDNX_t$ are statistically significant at any level.

Finally, the empirics confirms a domain traders mantra: COM is the most valuable TLD. Table6 shows pairwise price differences for identical SLDs under the 10 most frequently traded TLDs. The discount for NET is 75 percent, ORG is worth less than a fifth of COM, BIZ less than a tenth (please refer to Table6 for all TLD combinations). In the current econometric set-up, the TLD differences are assumed to be constant in time. DE domains trade for 37 percent less than their COM counterparts. This estimate might be inflated as the language of the SLD is not considered. This could lead to lower estimated discounts for ccTLDs from non-English speaking countries vs. COM whenever the SLD carries some meaning in the local language.

Table6: Pairwise price comparison of selected Top Level Domains (TLD), in %

	<i>net</i>	<i>org</i>	<i>info</i>	<i>mobi</i>	<i>biz</i>	<i>de</i>	<i>co.uk</i>	<i>es</i>	<i>eu</i>
<i>com</i>	-75 (-77;-72)	-84 (-86;-81)	-90 (-92;-89)	-97 (-97;-96)	-96 (-97;-95)	-37 (-42;-31)	-74 (-78;-70)	-86 (-90;-81)	-81 (-83;-78)
<i>net</i>		-39 (-47;-30)	-62 (-67;-56)	-80 (-84;-75)	-81 (-85;-75)	+90 (66;118)	+63 (31;102)	-36 (-55;-9)	-39 (-47;-29)
<i>org</i>			-48	-64	-63	+232	+124	-16	-10

	(-55;-39)	(-72;-54)	(-71;-53)	(179;295)	(73;189)	(-42;22)	(-24;6)
<i>info</i>		-32	-48	+342	+532	+60	+26
		(-45;-17)	(-59;-35)	(281;412)	(397;705)	(17;120)	(9;47)
<i>mobi</i>			-14	+223	+467	+73	+95
			(-34;14)	(154;311)	(320;666)	(23;143)	(51;151)
<i>biz</i>				+529	+643	+149	+227
				(386;715)	(401;1002)	(51;310)	(159;314)
<i>de</i>					+64	-58	-68
					(35;101)	(-68;-45)	(-72;-64)
<i>co.uk</i>						-68	-61
						(-79;-52)	(-69;-51)
<i>es</i>							-29
							(-51;4)

Notes: The matrix shows the estimated price differences (in percent) across TLDs based on the regression coefficients from (3); 95 percent confidence bounds in parenthesis. A NET domain, for instance, is estimated to be 75 percent more affordable than the COM equivalent, controlling for time trends and the Second Level Domain (SLD). In the current econometric setup, the TLD differences are assumed to be constant in time. Furthermore, the language of the SLD is not considered. This might lead to lower estimated discounts for ccTLDs from non-English speaking countries vs. COM whenever the SLD carries some meaning in the local language.

V Conclusion

This paper estimates the first constant quality price index for Internet domain names. The suggested index provides a benchmark for domain name traders and investors looking for information on price trends, historical return and fundamental risk of Internet domain names. It thereby increases transparency in the market for this newly emerged asset class and allows for comparisons to other investments. On average, domain prices grew by 6.6 percent per year in the last 7 years, exhibiting a boom and bust pattern that closely resembles the path of the overall IT industry. The strong correlations of domain

prices with the high tech economy and online advertisement revenues show that domain name buyers and sellers make economically motivated price decisions. Domain markets are not a cloud-cuckoo-land where dreamers trade esoteric goods at imaginary prices.

From a general asset pricing view, the price for an Internet domain name is the discounted future cash flows that can be generated from this domain. Domain prices are therefore forward looking, giving a indication of not only the current income but including expectations about future opportunities as well. Domain name prices can therefore serve as a fever curve capturing the well-being of Internet companies, online media providers and start-ups that base their business model on income from selling advertisement space. This sheds light on the prospects of small and medium sized online enterprises that are currently excluded by traditional stock-price indices.

Comparing the dynamics of the estimated index to fundamental economic variables suggests a regime shift to a new equilibrium between domain prices and advertising revenues after 2010. After the recovery from the financial crisis, domain prices do not grow as fast any more as the advertising spending. This shift is possibly caused by changes in the user flows caused by the growing importance of search engines and their algorithms. Jeong et al.(2012) for instance find that search engines channel the growing number of searches to relatively fewer domains: In 2010, the share of search results linking to the top 30 domains increased to 38percent, which is already 1.5 times higher than 2009 values. The concentration in traffic leads to a funnelling of advertising revenues on fewer domains, putting price pressure on the majority of domains. In addition, the exclusion of parked domains from search results (Singhal and Cutts,2011) put a dent in revenues from owning domains.

A cointegration analysis of primary and secondary domain markets reveals that domain registrations and prices are linked. Prices changes observed in the secondary markets and registrations

both depend on changes in the general demand for domain names. Unlike the market for real land, no zoning or other formal regulations restrict the creation of new locations on the Internet leaving availability of domains the only limit. The results show that this limitation is actually binding. If supply was unconstrained, re-sale prices for domains would not deviate far from registration fees and no statistical link between the two markets would be detectable.

Additionally, re-sale prices respond faster to changes in the underlying demand than registrations, indicating that traders incorporate new information on domain demand more rapidly than registrants.

Finally, the land-domain name analogy on which this paper rests can be extended from individual domains to agglomerations of domains. Top level domains like COM or NET are like cities in virtual space. As for real metropolitan areas, demand for space determines both the size of the virtual agglomeration measured in total number of domains registered (Figure1) and, simultaneously, the differences in prices paid for space in the centres of these cities (Table6). Higher demand for a specific extension results in both more sprawl and new initial registrations and in higher prices paid for locations within this agglomeration. This warrants a word of caution about the upcoming increase available extensions scheduled for 2013 and 2014 by the Internets governing body, ICANN. It will require millions of inhabitants for new online locations to support price-levels comparable to existing top level domains. Aspiring virtual land barons, beware!

Table3: Internet Domain Name Index (IDNX), 20062013

Date	IDNX	Date	IDNX
